The southern Gran Sabana region (SE Venezuela) holds a particular type of savanna characterized by the local occurrence of *morichales* (*Mauritia* palm swamps), in a climate apparently more suitable for rain forests. We present a paleoecological analysis of a Late Holocene sequence from Lake Chonita based on physical and biological proxies. Savannas dominated the region during the last millennia, but a significant vegetation replacement occurred around the lake in recent times. From 3.6 to 2.2 cal kyr BP the site was covered by a treeless savanna with nearby rain forests, and water levels higher than today until about 2.8 cal kyr BP. From 2.2 cal kyr BP onwards, the area has been under high fire incidence, likely determining the retraction of forest and a dramatic increase in the extension of *morichales*. The simultaneous appearance and the coincident trends of charcoal and *Mauritia* pollen supports the hypotheses about the potential pyrophilous nature of this palm and its recent expansion, probably linked to human activities. Since the beginning of these local fires, the situation has not changed until today, suggesting that the present-day Pemón culture - in which fire is an essential component- may have established in the site around 2000 years ago.

Lake Chonita

The palynological study of the upper part of the lake Chonita sequence, from southern GS, allows for the reconstruction of vegetation changes during the last three millennia. Although savannas were the dominant vegetation type, two different savanna landscapes are recognized: a treeless savanna with forests more extensive and/or closer than today prior to 2180 cal yr BP (with likely higher water levels prior to 2800 cal yr BP), and a savanna with *morichal*, under intensive fire regimes thereafter. The abrupt and dramatic increase of *Mauritia*, and the concomitant decrease of forest elements occurred around 2000 cal yr BP could have been caused by fire. At the same time, a shift to drier conditions than in the mid-Holocene has been reported in nearby localities suggesting that a regional climate change should also be considered, but given the preference of *Mauritia* for humid climates, the hypothesis of fire is better supported. The synchronous appearance of *Mauritia* and charcoal, together with the disappearance of forests, support the hypothesis of a potential pyrophilous nature of this palm (Montoya et al., 2009). The continuous occurrence of local fires during the last two millennia around Lake Chonita suggests the presence of human settlements well before the assumed colonization around the last centuries. The results presented here highlight the importance of the interplay between climate and fire to explain the present-day GS vegetation. The colonization of the GS by *Mauritia* appears to have occurred later than in the Colombian Orinoco Llanos, probably because of a later human occupation and the physical isolation of these savanna patches with respect to the main northern South American savanna areas. Further studies are required to test this hypothesis, but it seems that the present geographical patterns of *Mauritia*, and the monospecific communities it forms, are the result of the synergy between biogeographic, climatic and anthropogenic factors, with human-made fires as a major cause.

ProClim

### Background: post IR-IRSL

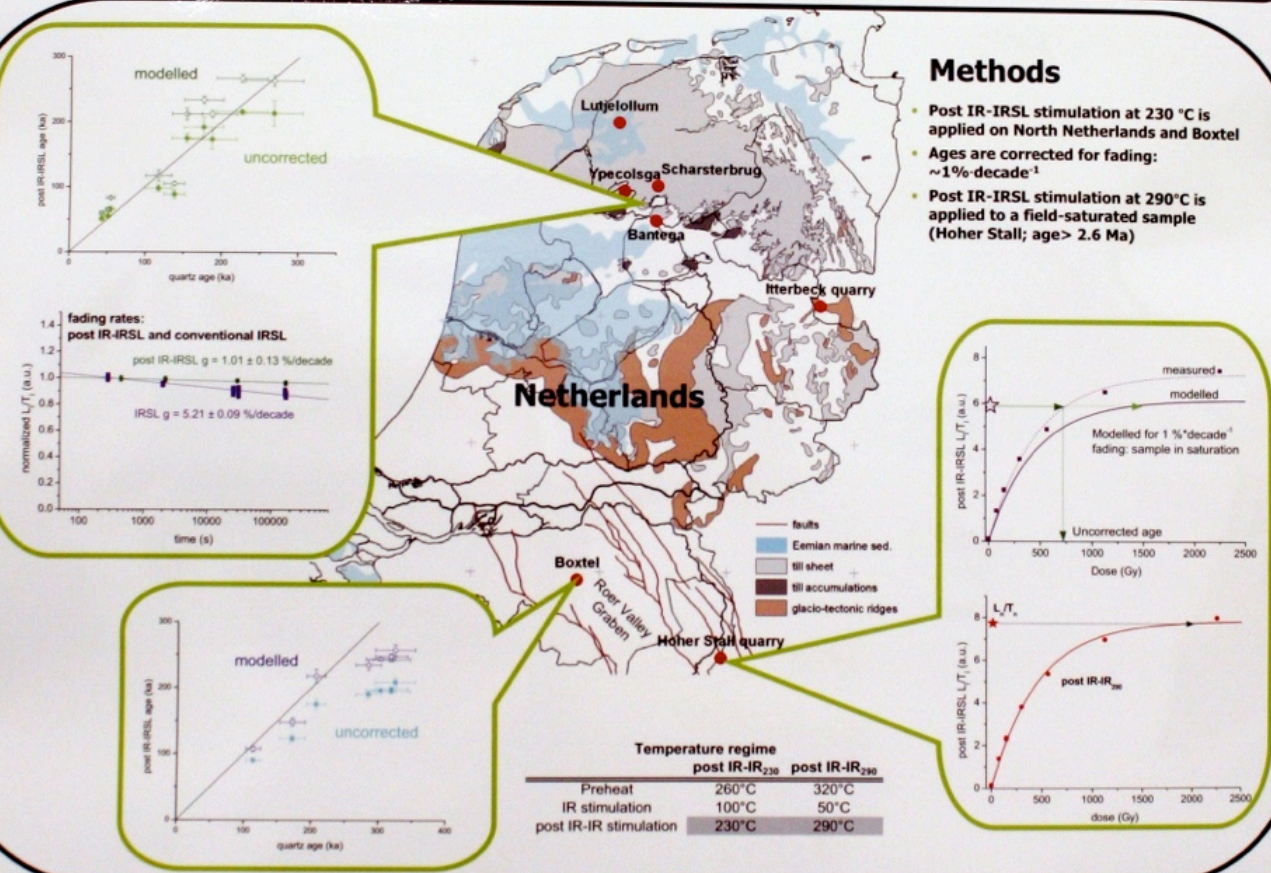

- Post IR-IRSL dating is a newly developed method for luminescence dating on K-feldspar (Thomsen et al., 2008)
- Selects the stable part of the IR-stimulated signal → anomalous fading is avoided!
- Post IR-IRSL replaces conventional IRSL combined with fading correction
- An IR-bleach erases the signal that is prone to fading; high temperature IR-stimulation probes the stable signal

### Goal

- To test post IR-IRSL dating on Late and Middle Pleistocene samples
- Post IR-IRSL ages are compared with:
  - Independent geological age constraints
  - Quartz OSL ages

### Methods

- Post IR-IRSL stimulation at 230 °C is applied on North Netherlands and Bostel
- Ages are corrected for fading:  $\sim 1\% \text{ decade}^{-1}$
- Post IR-IRSL stimulation at 290 °C is applied to a field-saturated sample (Hoher Stall; age > 2.6 Ma)

### Results

- Post IR-IRSL at 230 °C ages need fading correction, but correction is very small
- Post IR-IRSL less dependent on fading correction due to low fading rate
- Post IR-IRSL ages of oldest Bostel samples show small underestimation of quartz OSL ages
- Post IR-IRSL at 290 °C can correctly measure field saturation level
- Fading-corrected conventional IRSL results in large overestimation of ages

### Conclusions

- Post IR-IRSL dating is a robust way to determine the age of Pleistocene sediments up to  $\sim 500$  ka
- Post IR-IRSL ages agree overall with quartz OSL ages and with geological constraints
- Post IR-IRSL at 290 °C fully eliminates the need for fading correction, but does not improve underestimating ages obtained from corrected post IR-IRSL at 230 °C
- The use of conventional IRSL in combination with fading correction should be avoided

# Palaeoclimatic and Palaeoenvironmental history of the late Quaternary sediments from the Indian sector of Southern Ocean: Rock Magnetic and Geochemical Signals

M.C. Manoj<sup>1</sup>, M. Thamban<sup>1</sup>, N. Basavaiah<sup>2</sup> and Rahul Mohan<sup>1</sup>

<sup>1</sup> National Centre for Antarctic and Ocean Research, Headland Sada, Goa, India.

<sup>2</sup> Indian Institute of Geomagnetism, New Panvel (W), Mumbai, India.

## Introduction

Southern Ocean was a key element in the evolution of the late Quaternary millennial climate changes and represents a junction box of global conveyor-belt circulation. Our study attempts to evaluate the different environmental magnetic and geochemical parameters as palaeoclimatic proxy indicators in a well-dated sediment record from the Indian sector of Southern Ocean and to correlate with the major environmental changes other global palaeoclimatic records during the late Quaternary.

## Study Region

Fig. 1. Location map of the studied core

The Indian sector of the Southern Ocean is characterized by several circumpolar fronts.

### Major fronts:-

- Subtropical Front (STF)
- Sub-Antarctic Front (SAF)
- Polar Front (PF)

### Major water masses:-

- Antarctic Bottom Water (AABW)
- Circumpolar Deep Water (CDW)
- Antarctic Intermediate Water (AAIW)

## Materials and Methods

A 7.54 m long sediment core (SK 200/22a) collected from the Indian sector of Southern Ocean, located at 43° 42'S and 45° 04'E, onboard ORV Sagar Kanya (SK 200), was used for this study.

Chronological control was obtained by accelerator mass spectrometry (AMS) radiocarbon (<sup>14</sup>C) dates using two planktonic foraminifera species, *Globigerina bulloides* and *Neogloboquadrina pachyderma*. The radiocarbon ages were calibrated to calendar ages using Calib5.0.2 programme.

Fig. 2. Stratigraphic model for SK200/22a

Major proxy parameters studied in the core include:

- ✓ Environmental magnetic parameters using standard procedures.
- ✓ Inorganic element chemistry using ICPMS.
- ✓ Organic and inorganic carbon using TOC Analyser.
- ✓ The coarse fractions (>125µm) were studied for estimating the Ice Rafted Debris (IRD) content in the sediment.
- ✓ The stable isotope ( $\delta^{18}O$  and  $\delta^{13}C$ ) of *Neogloboquadrina pachyderma* tests using IRMS.

## Results and Discussions

Fig. 3. Profile of the environmental magnetic parameters

- **Magnetic Concentration** - The last deglaciation shows a rapid increase in values of  $\chi$ ,  $\chi_{ARM}$  and SIRM, with substantial increase between 18.5 and 13 kaBP.
- **Magnetic grain size**- Fine grained magnetic minerals during MIS 1 and early MIS 3 suggest a reduced eroding capability of the currents.
- **Magnetic mineralogy**- The high S-ratio and high Soft IRM values suggest that mineralogy is dominated by fine grained low-coercivity magnetite and titanomagnetite.

## Conclusions

- The magnetic,  $\delta^{18}O$  and  $CaCO_3$  records suggest that past changes in sea surface warming, intensity of ACC, calcite content and lithogenic input were closely interlinked and responded to the climatic changes in the southern hemisphere.
- The ice rafted debris record revealed major ice rafting events during 13-20 kaBP, 23-30 kaBP, 40-44 kaBP and 52-58 kaBP with an out-of-phase relation with magnetic (lithogenic) and calcite productivity.
- The timing and characteristics of the multiple proxy record reported here clearly indicate an out-of-phase north-south linkage through the bipolar seesaw mechanism.

## Acknowledgments

The authors are grateful to National Centre for Antarctic & Ocean Research (NCAOR), the Ministry of Earth Sciences (MoES), India and Indian National Science Academy (INSA) for providing with funds and supports.

Fig. 4. Downcore variations of productivity and lithogenic proxies

- The high Al normalized values of U, Mo, and V occur during glacial periods (MIS 2 and MIS 4) and certain intervals of MIS 3 reveals the existence of suboxic bottom waters.

• Geochemical proxies like Al and Fe, IRD and rock magnetic properties shows a substantial increase in lithogenic input between 18.5 and 13 ka BP (Fig. 4).

• Results showing high but variable opal, organic carbon and lithogenous fluxes during MIS 3 and LGM.

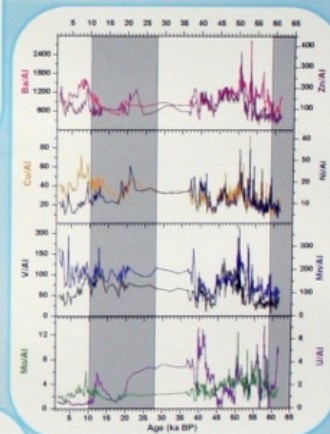

Fig. 5. Downcore variations of geochemical proxies

- ❖ Comparison of the magnetic and geochemical proxies revealed that the lithogenic input fluctuated in tandem with sea surface warming and calcite productivity.
- ❖ Periods of enhanced lithogenic input and calcite productivity were synchronous with the millennial-scale Antarctic warming events, indicating an Antarctic linkage.
- ❖ Major IRD events are clearly out-of-phase with the northern hemisphere Heinrich events.

PAST GLOBAL CHANGES

# A new method to investigate past grassland dynamics in South America based on Poaceae pollen grain size

Lisa Schüler and Hermann Behling

## INTRODUCTION

Despite the dominance of grassland ecosystems in South America during the Pleistocene and their high biodiversity, these biomes have received little attention so far. Not much is known about their past development, biodiversity and dynamic. However, due to the very uniform morphology of Poaceae pollen grains, it has been impossible so far to investigate palaeo-grassland with a palynological approach. In this innovative pilot study we attempt to distinguish between different South American grassland types in space and time based on morphological pollen characteristics of Poaceae.

Based on these circumstances we formulated the following Research Questions:

- 1) Is it possible to distinguish between grassland types in South America using quantifiable pollen morphological characteristics of Poaceae?
- 2) Are there spatial trends or patterns and what could they tell us?

## STUDY SITES

20 samples from 4 different grassland-types were investigated:

- ★ Páramo in S Ecuador (10 samples)
- ★ Campos in S Brazil (6 samples)
- ★ Campos de Altitude in SE Brazil (2 samples)
- ★ Pampa in Argentina (2 samples)

Fig. 1: Sites of investigated grassland types

## RESULTS

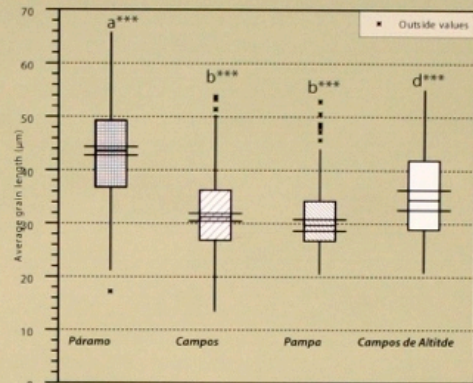

Fig. 3: Boxplot diagram on the average grain length per grassland type. Level of significance of differences: \*\*\*( $p < 0.001$ )

The statistical tests reveal highly significant differences in grain length between all grassland types except for Campos and Pampa (Fig.3). Grains from the Páramo are much larger than from any other grassland. Campos and Pampa have the smallest grains and Campos de Altitude assumes an intermediate position on the size scale. The variation of grain size within one grassland type is rather high.

The PCA based on the full dataset with samples shows differences between the grassland types (Fig. 4). The far right position of the Páramo scores is very conspicuous, here the largest pollen grains are found. Also, the highest score density is shifted into the range of larger pollen grains. The smallest grass pollen grains belong to the Campos. Also the other grassland types show distinct grain size distributions.

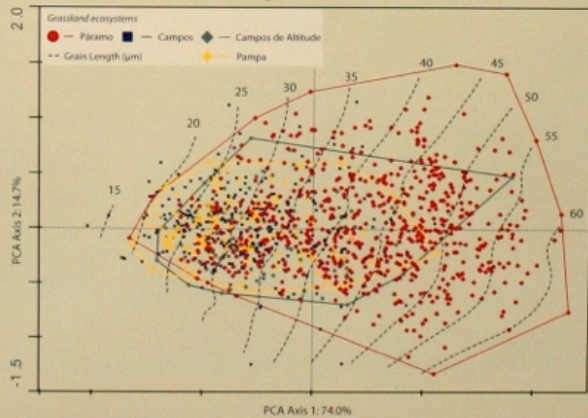

Fig. 4: PCA diagram of the full data set with LOESS model of grain length.

## CONCLUSION

The results of this pilot study show that it is possible to distinguish between South American grassland types using Poaceae pollen morphology. Assuming that a certain size range corresponds to a certain Poaceae taxa, we can derive different taxa compositions in the different grassland types. From our results we can also assume spatial and temporal patterns e.g. that the Campos taxa composition is more closely related to the one found in Pampa and Campos de Altitude, maybe being even a derivative of these. During cooler periods species from Pampa and Campos de Altitude might have moved to the warmer Campos area, comprising today's taxa composition.

**This approach has high potential to unravel so far inaccessible patterns and dynamics of biodiversity and taxa composition of palaeo-grasslands.**

## METHOD

5 parameters of at least 60 grains per sample were measured:

- 1) grain length
- 2) grain width
- 3) pore diameter
- 4) annulus height
- 5) annulus width

Fig. 2: Measured grain parameters

All grains were measured using a photo microscope under 400x magnification. A regression and principle component analysis (PCA) revealed the grain length as a representative parameter and then used for further analyses. The samples per grassland type were pooled. We applied statistical tests and multivariate data analysis to investigate

<sup>1</sup>Institute of Geographical Sciences, Interdisciplinary Centre for Ecosystem Dynamics in Central Asia (EDCA);

<sup>2</sup>School of Geography and Oceanography, Nanjing University, China

Freie Universität Berlin

### Background

The project aims to reconstruct the Quaternary landscape evolution of the north-eastern Tibetan Plateau, e.g. within the catchment of Lake Donggi Cona (35.3° N, 98.6° E, 4090 m a.s.l., Fig. 1). Changes in local base level control many geomorphological and sedimentological processes within a lake catchment and, hence, effect proxy generation and conservation in terrestrial archives. Lake level changes below the present level have already been presented in Dietze *et al.* (2010). Mischke *et al.* (2010) discussed indirect (i.e. ostracod) proxy evidences for lake status changes. Here, we present a first basin-wide view on higher lake levels from geomorphological and sedimentological evidences.

Fig. 1. Location of lake Donggi Cona at the Kunlun Fault and regional air mass boundaries on the Tibetan Plateau. After Böhner (2006), Fu *et al.* (2005).

### Methods

Nine on-shore terrace transects were mapped in detail in their geomorphologic context using tachymetry and differential GPS. On-shore lake sediments were described and sampled at high resolution at several outcrops and pits around the lake (Figs. 3-5).

Volume percentages of 85 grain size classes less than 2 mm were measured with a Coulter LS 200 laser diffraction particle size analyser. Geochemical composition was determined with an ICP-OES device. Future work will include a detailed interpretation of these data sets as they provide important environmental information.

Fig. 2. Overview of outflow area of lake Donggi Cona with two on-shore lake terraces containing paleolake sediments (8 in Fig. 5)

### Results

Fig. 3. Rare example for on-shore terraces (left) on the southern rim of Lake Donggi Cona (6 in Fig. 5), which is dominated by sediment erosion, as shown e.g. by an abrasion platform 10 m above the present lake level (a.p.l.) (right).

Fig. 4. At profile P14 lake sediments intercalate with floodplain and aeolian sediments at the 2<sup>nd</sup> largest inflow to lake Donggi Cona.

Fig. 5. Locations of investigated lake sediments (cf. Fig. 6) and terraces above the present level of lake Donggi Cona, NE Tibetan Plateau.

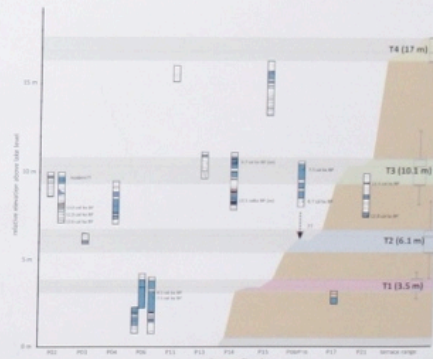

Fig. 6. Sketch of all lake sediment profiles within the range of related terraces above the present lake level. Mean calibrated 14C ages may include a potential reservoir age of ~2000 years.

Fig. 7. Profiles in T3 terrace showing intercalation of fluvial/alluvial and lacustrine sediments (P02, P21 in Fig. 5). Grain size distributions in P21 show a high content of silty aeolian material in the lake sediments.

Four on-shore terraces above the present lake level were mapped around the lake, showing different grades of erosion. A vertical displacement by tectonic forcing can be excluded. Lake sediments above the present lake level are intercalated with fluvial, alluvial and littoral sediments at several locations. They give detailed information on environmental processes for the Early and Mid-Holocene time slices. However, they are often discontinuous and post-depositionally overprinted by permafrost and/or earthquakes – allowing only relative reconstructions.

Future work will focus on the interpretation of the lab data. Modelling of grain size end-members with the algorithm of Dietze *et al.* (in rev., Sed. Geol.) will be combined with the uncertainties in age data, which will lead to new probability-based approaches of interpreting environmental processes.

Fig. 8. Former lake extensions above present lake level based on SRTM DEM and reconstructed from geomorphological mapping and remote sensing. Age estimation after Fig. 6.

Fig. 9. Valley with lake Donggi Cona's 2<sup>nd</sup> largest inflow. Terraces of 10 m a.p.l. indicate past highly dynamic sedimentation and erosion processes.

## 1. Introduction

Kestanel quartz-monzonite, outcropping in the Ezine village of Çanakkale, Turkey (Fig. 1, Fig. 4) was operated by the Romans for the production and export of building stones since ancient times. Today, remnant building stones can still be found in the ruins of these quarries, whose extent and operation periods are unknown. However, a Roman period can be

estimated between 310 BC (Riel, 1997) to 420 AD (Akçar et al., in prep.), according to the foundation and decay of *Alexandria Troas*.

Can cosmogenic  $^{10}\text{Be}$  help to quantify the chronology of quarrying in this area?

Fig. 1: Location of the study area.

Fig. 2: Sampling sites at Yedi Taşlar quarry with seven columns of 12.5 m length (Akçar et al., in prep.).

Fig. 3: Sampling sites at the quarry near Zurnacıdeğirmeni with columns of 12 m length.

Fig. 4: Overview of study area with sampling sites, mapped area and ancient cities.

## 2. First $^{10}\text{Be}$ Results

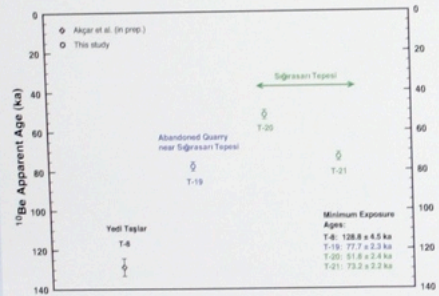

Fig. 5: Comparison of minimum rock surface exposure ages of this study and Akçar et al. (in prep.).

According to our first  $^{10}\text{Be}$  results from bedrock samples, the landscape surface in the study area is at least 130 ka old (Fig. 5). The exposure ages of the worked steps at the Yedi Taşlar quarry vary from 7 ka to 10 ka, whereas exposure ages of worked steps at the quarry near Zurnacıdeğirmeni fluctuate between 4 ka and 5 ka (Fig. 6). Despite the difference, both quarries show significantly older ages than 310 BC (Riel, 1997) to 420 AD (Akçar et al., in prep.) based on archaeological data. Therefore, sampled working steps contain a significant amount of inherited cosmogenic  $^{10}\text{Be}$  in our study area.

Fig. 6: Comparison of analysed working steps of this study and Akçar et al. (in prep.). Note that T-7 is a natural step.

## 3. Depth Profiling

As we are not able to directly exposure date operation periods of these quarries, we sampled a recently abandoned quarry at Sığrasan Tepesi near Akçekeçili to model the variation of  $^{10}\text{Be}$  with depth. Eight samples were taken (Fig. 7), analysed and sample

depths corresponding concentrations are plotted in Fig. 8. As we can see is in a depth of 14.5 m still a concentration around 14000 atoms/gram quartz measurable.

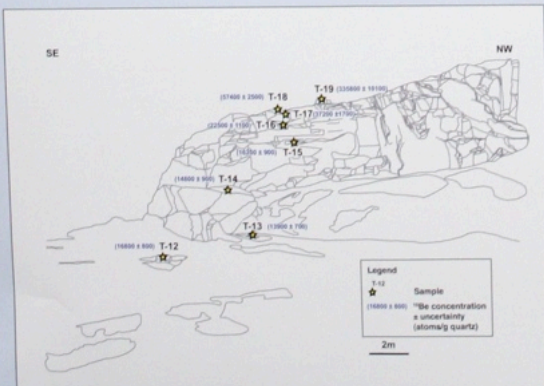

Fig. 7: Depth profiling samples indicated by stars in a recently abandoned quarry at Sığrasan Tepesi near Akçekeçili. The values in brackets are the measured  $^{10}\text{Be}$  concentrations.

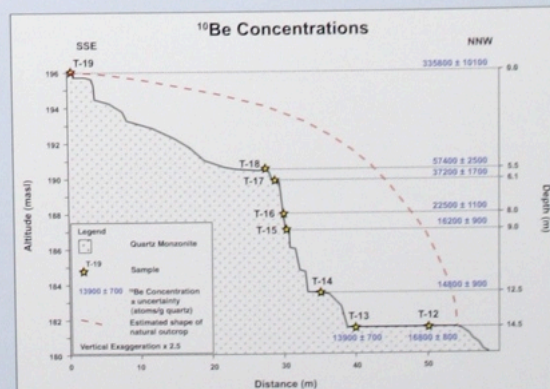

Fig. 8: Depth profiling samples indicated by stars in a recently abandoned quarry at Sığrasan Tepesi near Akçekeçili. Measured  $^{10}\text{Be}$  concentrations are plotted at their corresponding depth. The red dashed line indicates the estimated shape of the natural outcrop.

## 4. Conclusion

The landscape surface is at least 130 ka old in our study area. Roman quarries in the Kestanel quartz-monzonite can not directly be exposure dated with in-situ produced cosmogenic  $^{10}\text{Be}$  surface exposure dating due to inheritance. Samples for a depth profile show at 14.5 m depth still concentrations of 14000 atoms/gram quartz.

## 5. Outlook

In the following, a model of the  $^{10}\text{Be}$  concentration with depth in the Kestanel quartz-monzonite will be developed with which we will be able to correct our working step ages for inheritance. Thus, we finally will be able to calculate exposure ages to determine operation periods of Roman quarries in our study area.

ID 2010  
Isotope hydrology as a tracer of Quaternary climates

## Questions

Does sea surface salinity in the northern East China Sea oscillate in harmony with Dansgaard-Oeschger cycles during Marine Isotope Stage 3?

It has been suggested that changes in fresh water discharge from the Yellow and Yangtze Rivers attributed to deposition of dark and light layers in the Japan Sea, which are in association with Dansgaard-Oeschger (D-O) cycles [Tada et al., 1999]. This study aims to reconstruct sea surface salinity in the northern East China Sea in order to test this scenario.

## East China Sea to Japan Sea

Temporal variation patterns of oscillations in grayscale ( $L^*$ ) of the hemipelagic sediments in the Japan Sea are coincide with the D-O cycles in Greenland ice cores. The grayscale principally reflect organic carbon contents ( $C_{org}$ ) that was controlled by primary production during the MIS3 [Tada et al., 1999]. Deposition of dark layers contain higher  $C_{org}$ , and were attributed to nutrient-rich and low-salinity water from the East China Sea.

Fig. 3 Photo of a sediment in the Japan Sea, water depth of 2074 m.

## Oceanography

Fig. 1 Present current system in the East China Sea after Ichikawa and Beardsley [2002] and location of cores KR07-12.

## Summer at present

Surface salinity in the northern East China Sea  
Discharge of the Yangtze River (Changjiang)  
Rainfall in the catchment area of Yangtze River  
(Delcroix and Murtugudde, 2002)

Fig. 2 Locations of the studied site (KR07-12), MD2407 in the Japan Sea (Kido et al., 2007) and Hulu Cave (Wang et al., 2001). Shaded zone represents the drainage area of the Yangtze River. 80 m sea-level drop corresponds MIS3.

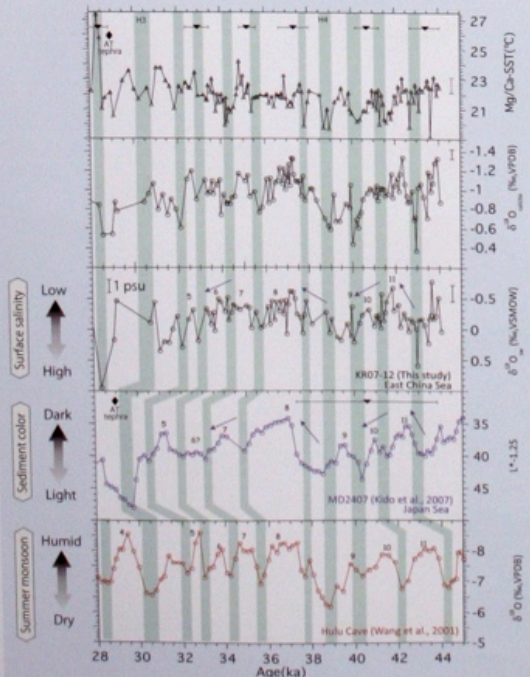

## Age model

2-4 mg of planktic foraminifera *N. dutertrei* were used for the AMS measurement.  
AMS  $^{14}C$  ages were converted to calendar ages by using calib. 6.0 with marine 09 and local reservoir correction of +29 yr.

Fig. 4 A depth versus calendar age for core KR07-12. Error bars show 2 $\sigma$  error. -15 cm/ky, -70 cm/ky, -40 cm/ky are linear sedimentation rate for the Holocene, early deglaciation, the last glacial period, respectively.

## Results

### Mg/Ca in fossil foraminiferal calcite

$SST = \ln(Mg/Ca / 0.38) / 0.089 - (1)$  [Hartings et al., 2001]  
SST: Sea surface temperature  
Planktic foraminifera "*G. ruber*"  
① Dwelling: upper 30 m in water column  
② Season: May to August (Xu et al., 2005)

### Oxygen isotope ( $\delta^{18}O$ )

$SST = 14.9 - 4.8 (\delta^{18}O_{calc} - \delta^{18}O_{sw}) - (2)$  [Bemis et al., 1998]  
 $\delta^{18}O_{sw}$ : Oxygen isotope of ambient seawater  
Locally,  $\delta^{18}O$  is linearly related to sea surface salinity [Oba, 1998].  
Global ice volume effect was corrected by Waelbroeck et al., 2002)

## Discussions

- Approximately 1‰ amplitude of variations in surface salinity variations is equivalent to 5 psu in salinity, if the modern salinity- $\delta^{18}O_{sw}$  relationship [Oba, 1998] is used.
- From 44 to 38 ka, millennial-scale variations in  $\delta^{18}O_{sw}$  in the northern East China Sea correlate well with those in  $L^*$  in the Japan Sea, although the interstadial #10 and #11 are ~1 ky younger than those in Hulu Cave due to the error of the age models. Stadial #10 is recognized clearly in the East China Sea and in the Japan Sea, while that is not obvious in Hulu Cave.

## 1. Temperature

- SST oscillates by ~3°C during MIS3
- Lower SST correspond to Heinrich events #4 and #3, and D-O stadial #5, 6, 7, 10, and 11. It suggests **teleconnection between the East China Sea and north Atlantic climate.**

## 2. Salinity ( $\delta^{18}O_{sw}$ )

- $\delta^{18}O$  of seawater ( $\delta^{18}O_{sw}$ ) oscillates by ~1‰ during MIS3.
- Heavier  $\delta^{18}O_{sw}$  corresponds to Heinrich events #4 and stadial #3, 5, 6, 7, 10, and 11.
- Temporal variation in  $\delta^{18}O_{sw}$  agrees well with that of  $L^*$  in the Japan Sea**, supporting that the nutrient-rich coastal water of the East China Sea entered to the Japan Sea and caused deposition of dark layers.

- From 38 to 28 ka, interstadial #6 is obvious in  $\delta^{18}O_{sw}$  in the East China Sea while that is not clear in  $L^*$  of the Japan Sea sediments.

## Conclusion

Our results support the idea that the intrusion of the East China Sea coastal water caused repeated deposition of dark layers in the Japan Sea on millennial-scale during MIS 3.

# Ice-free areas have existed through multiple glacial cycles on the Antarctic Peninsula.

<sup>1</sup>Rebecca Rixon, <sup>2</sup>Christopher Fogwill, <sup>3</sup>Morag Hunter, <sup>4</sup>Pete Convey, <sup>5</sup>Sheng Xu, <sup>6</sup>Finlay Stuart, <sup>5</sup>Christoph Schnabel

## 1. Introduction

This study represents the first attempt to constrain the long term evolution of the Antarctic Peninsula Ice Sheet (APIS) in the Larsen Embayment and provides the first terrestrial geological evidence of ice-free areas within the APIS over multiple glacial cycles. The APIS is poorly constrained in terms of its volume and extent at the Last Glacial Maximum (LGM). Current Antarctic Ice Sheet models show complete ice coverage over the Antarctic Peninsula and extensive ice sheet thickening during the Last Glacial Maximum (LGM). However, evidence from biological refugia suggests areas of Antarctica have been ice free for millions of years (Convey *et al.* 1998).

## 3. Results

### Geomorphological mapping

Geomorphological mapping in the region identified a Maximum Altitude of Erratics (MAE) in the Eternity Range (Figure 3). Glacial erratics were located towards the summit of Mount Sullivan and on the summits of Engel Peaks (Figure 3). Across the site location deeply weathered and pitted surfaces were identified, which were further exaggerated above the MAE.

Figure 3. Illustrates the maximum altitude of erratics in the study location. Figure also illustrates the approximate location of samples. For full details of the samples altitude please see Figure 6.

### Cosmogenic isotope analysis

<sup>10</sup>Be and <sup>26</sup>Al data suggests a simple record of ice sheet thinning in this region of the Antarctic Peninsula (Figure 4). While <sup>21</sup>Ne and <sup>10</sup>Be analysis suggests the lower altitudinal samples N.8.18 and N.8.36 have a more complex deglacial history (Figure 5).

Figure 4. Samples N.8.18, N.8.28, N.8.29, N.8.36 all plot within the "island" suggesting a simple exposure history.

Figure 5. Samples N.8.18, N.8.28, N.8.29, N.8.31, N.8.36. Samples above the MAE (Figures 3 and 6) show simple ice sheet history, while the lower samples show a more complex history.

Sample ID	Altitude (m.a.s.l.)	Height above current ice sheet (m)	Exposure age ( <sup>21</sup> Ne results)	Exposure age ( <sup>10</sup> Be, <sup>26</sup> Al results)
N.8.31	2229	729	2.8Ma ± 61.3Ka	2.6Ma* ± 467Ka
N.8.29	2142	642	1.9Ma ± 57.4Ka	1.3Ma ± 226Ka
N.8.28	2104	504	1.8Ma ± 54.3Ka	1.1Ma ± 171Ka
N.8.36	1969	469	1.1Ma ± 37.1Ka	620Ka ± 86Ka
N.8.18	1952	452	1.4Ma ± 44.4Ka	682Ka ± 77Ka

Figure 6. Exposure ages above and below the Maximum Altitude of Erratics. <sup>21</sup>Ne data was calculated in CosmoCalc. <sup>26</sup>Al and <sup>10</sup>Be ages were calculated in Chronus using a time-dependent scaling scheme and Lal and Stone's scaling scheme. Erosion for all samples in Figure 6 are zero. The red line on the table corresponds with the line of maximum erratics shown in Figure 3.  
 \*Sample N.8.31 has not been tested for <sup>26</sup>Al, therefore the exposure age shown is calculated using <sup>10</sup>Be data only.

Exposure ages obtained from analysis of <sup>21</sup>Ne and twinned <sup>10</sup>Be, <sup>26</sup>Al data above the MAE correspond with each other and suggest areas of the Antarctic Peninsula have remained ice free throughout multiple glacial cycles. <sup>21</sup>Ne ages below the MAE are much older than the <sup>10</sup>Be, <sup>26</sup>Al data suggesting the <sup>21</sup>Ne data is picking up an older glacial signal due to <sup>21</sup>Ne inheritance in the younger samples.

## 2. Methods

Field investigations were undertaken in the Eternity Range, Northern Palmer Land (Figure 1). A series of glacial erratics and bedrock samples were taken for cosmogenic isotope analysis. Using unstable cosmogenic isotopes <sup>10</sup>Be and <sup>26</sup>Al and stable cosmogenic isotope <sup>21</sup>Ne we reconstructed the deglacial history of this sector of the Antarctic Peninsula.

Figure 1. Location of study highlighted.

By using an unstable multi-isotopic approach we were able to determine:

- 1) If the area had experienced a simple/ complex deglacial history
- 2) If the area had been covered in cold ice
- 3) Erosion rates on the rock surfaces

When low erosion rates were applied to the rock surfaces the oldest samples in the study reached complete isotopic saturation, so cosmogenic <sup>21</sup>Ne had to be used to look at the longer-term history of this section of the APIS.

Figure 2. Sampling in the Eternity Range. Geological samples were collected across Mount Faith, Mount Sullivan and Engel Peaks. The "dip-stick" sampling approach was adopted to measure the maximum ice extent and thinning rates of the ice sheet. A total of 39 samples were taken for cosmogenic isotope analysis. This poster shows the results for the 5 highest altitudinal samples only.

## 4. Conclusions

- Summits in the Eternity range have remained ice-free for multiple glacial cycles
- <sup>21</sup>Ne data from below the MAE produces older exposure ages compared to <sup>10</sup>Be, <sup>26</sup>Al exposure ages, suggesting <sup>21</sup>Ne inheritance
- This region of the Antarctic Peninsula has experienced much less ice thickening at the LGM than LGM ice extent models suggest

The results from this research suggest that in this sector of the APIS volume changes were far more muted than those recorded on the western fringes. This may reflect precipitation starvation due to the build up of a large independent ice dome over Alexander Island and in the vicinity of George VI Sound. This restricted ice sheet thickening to the east and preserved ice-free areas in this sector of the APIS over multiple glacial cycles.

## 1. Quest for the Oldest Ice

The Allan Hills blue ice area, located on the western flank of the Convoy Range of the Trans-Antarctic Mountains (Figure 1), may be able to provide a high-resolution record of great antiquity suitable for paleoclimate reconstructions. Ages from a micro-meteorite layer embedded in the ice and an individual meteorite indicate that ice as old as 2.5 Ma may be present at the surface. Radiometric terrestrial ages of meteorites and ice flow rates based on strain grids suggest continuous ice ages of 0-1.0 Ma.

Multi-million year records from marine sediments have hinted at possible drivers of climate, but their relatively low resolution and lack of direct proxies for reconstructing atmospheric chemistry make deciphering the interactions between these drivers difficult. Increased resolution and direct atmospheric proxies are available in ice cores; however, the longest existing record (EPICA Dome C (EDC)) only reaches 800 ka. Extending this record will greatly aid efforts to elucidate the factors controlling climate dynamics.

Figure 1: The Allan Hills Blue Ice Area is an anomalous mass-loss region within the accumulation zone of the East Antarctic Ice Sheet. Here sub-surface topography redirects slowly moving deep ice to the surface, where slope and strong katabatic winds combine to expose old ice.

## 2. Surface Ice Sampling

An estimated ice flow path through the Allan Hills Main Ice Field (MIF) was established in 2004 using topography produced from kinematic GPS surveying. In order to determine if surface ice along that path contained an undisturbed sequential environmental record, chips of ice were collected from 3-4cm depth every 10m along the flowline in the manner shown at right (Figure 2).

Figure 2: Chips of surface ice are collected in the Allan Hills Blue Ice Area. The ice appears blue because solar radiation is absorbed in the red part of the spectrum and reflected in the blue. The lightness of the color results from uniform scattering of light by enclosed bubbles.

Note the presence of mountains and nunataks in the photo background. These features and their sub-surface counterparts allow old ice to be directed to the surface and sit stagnant for long periods of time.

## 3. Oxygen Isotopic Composition and Chemical Analysis

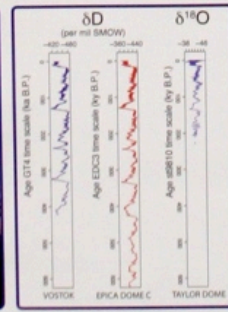

Figure 3: Surface samples were collected every 10m along the estimated flowline (dotted path) in the Allan Hills MIF. Direction of ice flow is roughly from the upper right to lower left of the image, with ice being near stagnant closest to the nunatak. Yellow dots indicate the location of shallow cores analyzed for soluble ion and trace element chemistry.

In central East Antarctica, the transition from glacial/inter-glacial conditions is recorded by a 5 ‰ or more increase of the abundance of  $\delta^{18}O$  in the ice over a relatively short depth interval. The range of the  $\delta^{18}O$  values within the 536 samples analyzed fits this observation and are similar to those found in the glacial/inter-glacial cycles of the Vostok, Taylor Dome, and EDC cores (Figure 4), suggesting that intelligible information about the climate history or structure of the ice sheet is preserved within the surface ice of the Allan Hills MIF. This is partially confirmed by ice core chemistry as those ice cores collected from glacial sections of the path have higher dust concentrations than the inter-glacial sections (with the exception of Core 3). More sections from a second season of collection will be analyzed in coming months.

## 4. Ice Coring and Future Work

One of the main challenges of the project will be to determine an accurate chronology along the flowline. To accomplish this task a multi-prong approach is being used. <sup>40</sup>Ar/<sup>39</sup>Ar measurements are being carried out at Princeton University, radiometric meteorite ages are being incorporated in a simple ice-flow model, and tephra layers that intersect the flowline are being dated. Additionally, a 225-meter ice core was drilled at a bedrock high along the flowline and a 15 cm resolution  $\delta^{18}O$  profile is being created from that core. By matching that profile with the surface profile in Figure 3 and with deep core profiles, such as those at left, a relative time-scale can be determined. Chemical analysis of selected sections of the 225-meter core will also be conducted.

Figure 4 (Far Left): Ice coring in the Allan Hills.

Figure 5 (Left): Down core isotope records from Vostok, Taylor Dome and EDC.

Figure 6 (Right): Cartoon version of how surface isotope record will be matched with forthcoming down-core isotope record.

# Lateglacial temperature and vegetation in western Ireland

Nelleke van Asch<sup>1,\*</sup>, Arthur F. Lutz<sup>1</sup>, Miriam C.H. Duijkers<sup>1</sup>, Oliver Heiri<sup>2,3</sup>, Stephen J. Brooks<sup>4</sup> and Wim Z. Hoek<sup>1</sup>

## INTRODUCTION

Here we present a high-resolution reconstruction of Lateglacial summer temperature changes and vegetation development in western Ireland. The study site is located close to the Atlantic Ocean, which makes its vegetational history exceptionally sensitive to climatic changes associated with changes in ocean circulation.

For the first time, we quantify summer temperature changes associated with observed changes in the Lateglacial vegetation development.

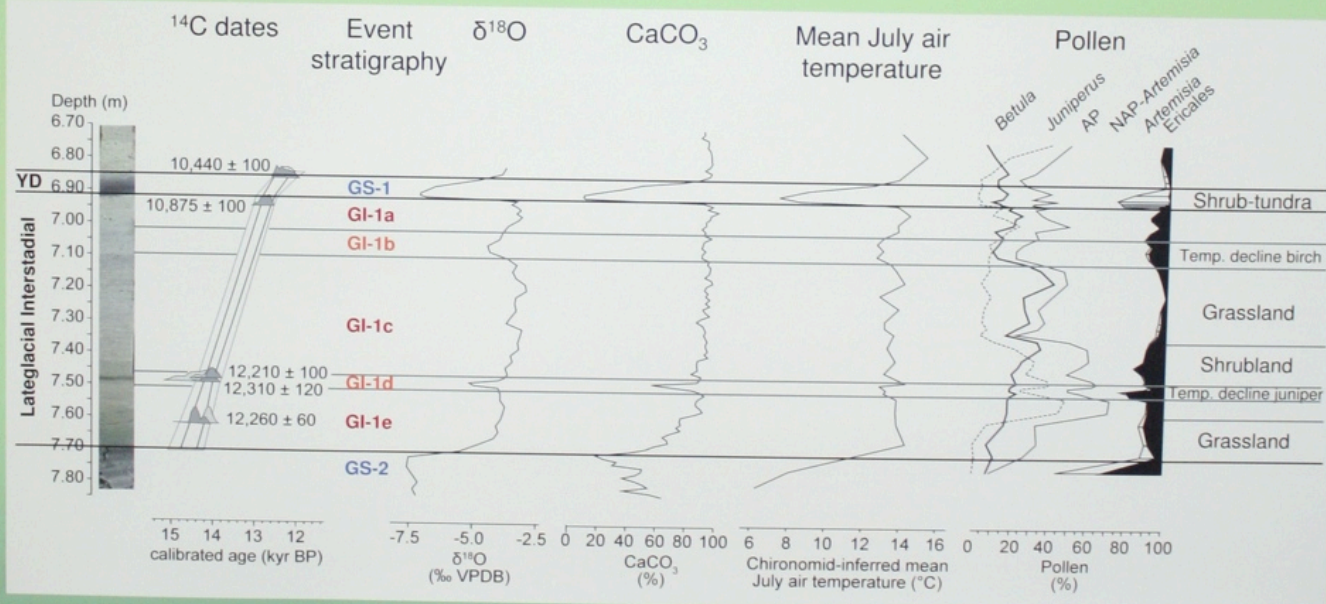

## RESEARCH SITE AND METHODS

We obtained a lacustrine sediment record from Fiddaun, western Ireland (53°00'56"N, 08°52'03"W).

The core was analysed for lithology, oxygen isotopes of bulk carbonates, fossil chironomids and pollen; chronology was based on radiocarbon dates. Chironomid assemblages were used to infer mean July air temperatures.

## RESULTS

## DATA SUMMARY AND CONCLUSIONS

- Mean July temperatures of ~12.5-14.5 °C are reconstructed for the Lateglacial Interstadial.
- Two short-lived cold oscillations are discerned in the Interstadial, these are correlated to GI-1b and GI-1d.
- These cold oscillations led to a temporary reduction of juniper and birch shrub regeneration.
- It seems the first oscillation (GI-1d) was the more severe in western Ireland, as carbonate precipitation decreased during this event.
- The transition to grassland during the Interstadial was not associated with decreasing summer temperatures.
- Younger Dryas July temperatures decreased to ~7.5 °C, carbonate precipitation stopped and grassland was replaced by shrub-tundra.

# Holocene flood frequency and redox-state evolution in meromictic Lake Cadagno (Swiss Alps)

Stefanie B. Wirth<sup>1</sup>, Adrian Gilli<sup>2</sup>, Helge Niemann<sup>2</sup>, Tais W. Dah<sup>3</sup>, Moritz F. Lehmann<sup>2</sup>, Flavio S. Anselmetti<sup>4</sup>

<sup>1</sup> Geological Institute, ETH Zurich; <sup>2</sup> Department of Environmental Sciences, University of Basel; <sup>3</sup> Institute of Biology and NordCEE, University of Southern Denmark; <sup>4</sup> Department of Surface Waters, Eawag, Swiss Federal Institute of Aquatic Science and Technology

## Introduction

Figure 1: Bathymetric map of Lake Cadagno with seismic grid and coring area.

Lake Cadagno is a meromictic high-alpine lake situated in the Piora valley in the Southern Alps of Switzerland (1921 m asl, 0.26 km<sup>2</sup>, max. water depth 21 m).

The inflow of salt-rich waters from subaquatic springs results in a permanent chemocline at 11 m, with anoxic bottom waters and a diverse anaerobic community of bacteria at and below the redox-transition zone. The modern redox conditions in Lake Cadagno are well studied, however, hardly anything is known about the paleoenvironmental conditions of the lake throughout the Holocene.

With this study we address the following questions:

- ▶ When did the chemocline form?
- ▶ Has it persisted since its formation?
- ▶ How frequent are flood events during the Holocene and do underflows affect the stability of the chemocline?

Figure 2: Sketch of present redox conditions and stratification in Lake Cadagno.

## Formation of the chemocline

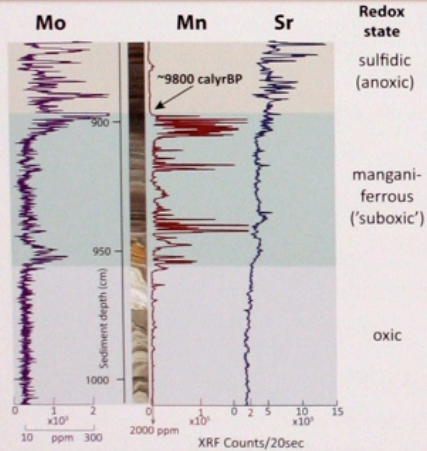

Figure 3: XRF core scanning data illustrating the formation of the chemocline.

The transition from oxic to anoxic conditions, including the formation of the chemocline, can be tracked in the XRF core scanning data.

- ▶ **oxic:** low Mo and Mn counts
- ▶ **manganiferrous:** high Mn counts, Mo counts begin to rise
- ▶ **sulfidic:** increase in Mo counts, decline in Mn
- ▶ **Sr:** possibly indicates the activation and the inflow of the subaquatic springs

The chemocline was fully established ~9800 cal yr BP. Before, the manganiferrous conditions persisted about 1000 years, providing a time frame for the chemocline formation.

## Holocene flood record & continuing sulfidic conditions

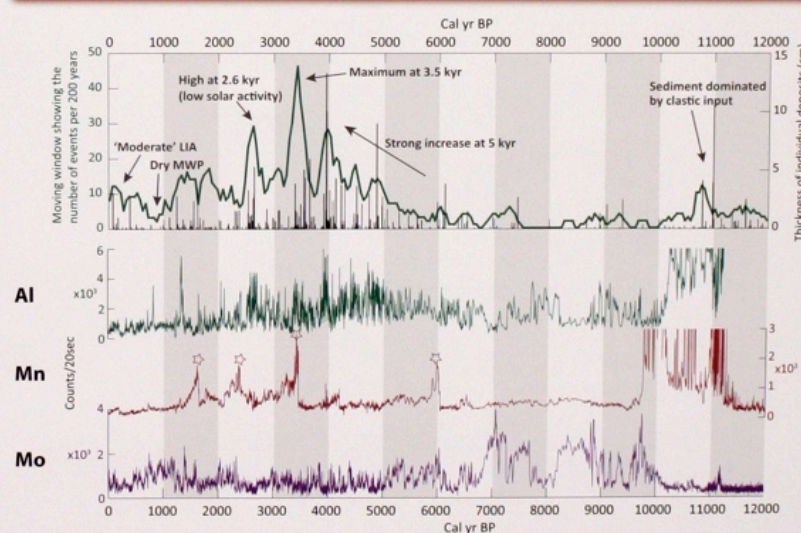

Figure 5: Holocene flood record and XRF data presenting detrital input and continuous anoxic conditions.

The Holocene **flood record** is characterised by a strong increase in flood frequency at 5 kyr and maximal flood activity between 2.5 and 4.5 kyr.

▶ **Al** as a detrital element reflects the clastic input delivered by the flood-induced underflows.

The **chemocline** and the **sulfidic conditions** have persisted throughout the Holocene.

- ▶ Moderate peaks of **Mn** (☆) during the Holocene indicate 'short-term oxygenation events' generated by mass-movements and intense flooding periods.
- ▶ Holocene **Mo** concentrations indicate persistent sulfidic conditions. However, periods of frequent flooding can reduce Mo burial by a factor 2.

## Hypothesis for Mo and Mn behaviour during the three redox states

**Oxic:** Mo occurs in its dissolved state, Mn-oxides are sedimented but partly reduced and Mn<sup>2+</sup> is released from the sediment.

**Manganiferrous:** Intensified Mn-cycle due to more reducing conditions. Mo starts to be partially sulfidized and adsorbed to particles.

**Sulfidic:** Mn mainly occurs in its reduced form Mn<sup>2+</sup>. Mo burial by sulfidization and adsorption to particles is intensified.

### What could have triggered the formation of the chemocline?

- ▶ Climate warming: warming of surface waters leads to stronger density gradient in the water column.
- ▶ Activation of subaquatic springs: the input of salt-rich water also leads to a stronger density gradient. This may as well be a signal of climate warming.

# Vegetation Variations in Dryland Systems from 1982 to 2006, with a Special Reference to the District of Xilin Gol, China

Hongwei Li, Xiaoping Yang

Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, P.O. BOX 9825, Beijing 100029, China

## Introduction

Located in the east margin of Gobi Desert, Xilin Gol is a transition region between steppe and desert. Steppe, desert-steppe and sandy land are three main subsystems in this region (Fig. 1). In this study, AVHRR NDVI data, covering from 1982 to 2006 in time, are used to investigate dry land's response of vegetation dynamics to climate change.

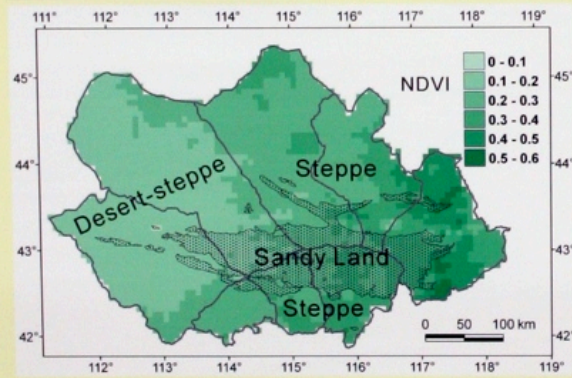

Fig. 1 Location and mean annual growing season (from April to October) NDVI of the study area

## General trend of NDVI

In terms of annual mean growing season NDVI, areas with increasing trend of NDVI are much larger than those with decreasing trend, which are 7% and 0.6%, respectively (Fig. 2).

Fig. 2 Significant trend of annual mean growing season NDVI ( $p < 0.05$ )

## Factors analysis

Rainfall is the crucial determinant of the NDVI variation, especially to the desert-steppe (Fig 3 A).

In contrast to rainfall, the correlation between NDVI and temperature is negative in the study area (e.g. Fig. 3 C). And the warming trend of the beginning and ending of the growing season would be of benefit to the dryland systems, except

for the desert-steppe, (Fig. 3 B and D).

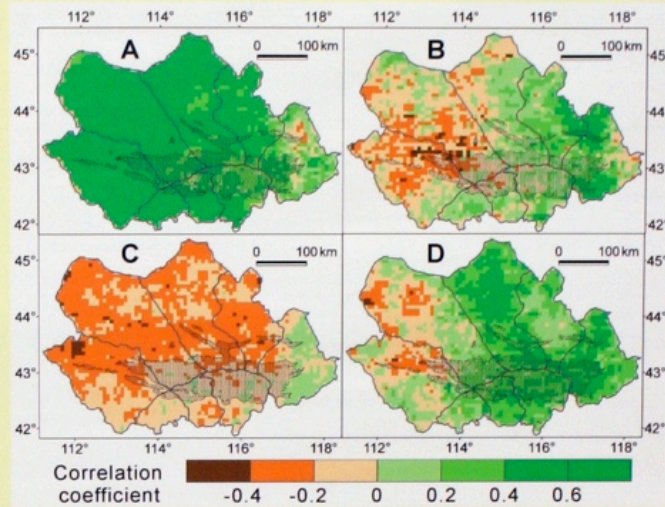

Fig. 3 Correlation between (A) annual rainfall and growing season NDVI, monthly mean temperature and NDVI of (B) April, (C) August, and (D) October.

## Stability of the dryland systems

By comparing NDVI dispersion and anomaly degree in response to the fluctuant climate and drought, the stability of the different dryland systems was discussed. It is shown that sandy land is relatively stable in the three subsystems (Fig. 4)

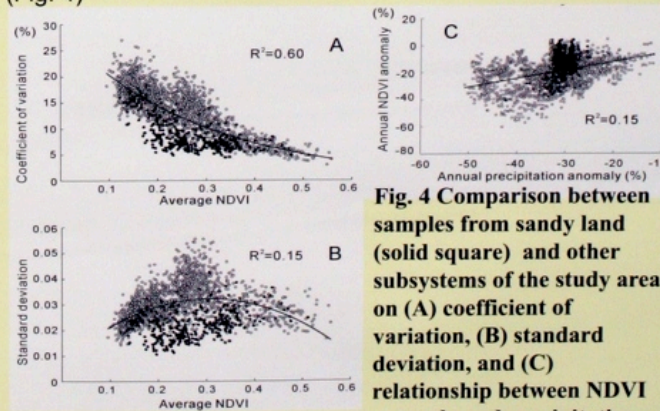

Fig. 4 Comparison between samples from sandy land (solid square) and other subsystems of the study area on (A) coefficient of variation, (B) standard deviation, and (C) relationship between NDVI anomaly and precipitation anomaly in 1989.

## Conclusions

Although some area experienced increase of NDVI in the past 30 years, it could not be attributed to the rising temperature occurred in the study area. Generally, the warming trend of the climate would lead to the degradation of vegetation in the dryland systems, and the desert steppe is the most fragile subsystem. Sandy land is the most stable one in the dryland systems. Thus, in the future, much more attention should be paid on the steppe and desert-steppe to control desertification.

# Medieval Climatic Anomaly and Little Ice Age Dune Activity in the Arkansas River Valley, Central Great Plains, USA

Alan F. Halfen (afhalfen@ku.edu) and William C. Johnson (wcj@ku.edu)  
University of Kansas, Department of Geography, 1475 Jayhawk Blvd., Lawrence, KS 66045, USA

## INTRODUCTION

- The Hutchinson, Great Bend Sand Prairie, and Arkansas Valley dunefields are prominent features in the Arkansas River valley.
- Collectively, these features cover more than 1,000,000 ha.
- In addition, these dunefields span a 400-km east-west precipitation gradient with precipitation decreasing by 360 mm to the west.
- The dramatic precipitation gradient, together with the size and location of these dunefields make them crucial to understanding spatial aspects of Great Plains drought.

## METHODS

- We present a new chronology of dune activation derived from new AMS <sup>14</sup>C, 110 new OSL ages, and previously reported ages.

1.2m section exposing dune and alluvial stratigraphy in the Arkansas Valley Dunefield [left]. Bucket auguring for optical dating samples in the Hutchinson Dunefield [right].

## ARKANSAS RIVER VALLEY

## CHRONOLOGICAL RESULTS

- Age results indicate that dunefields in the Arkansas River valley were active during the early to middle Holocene.
- The vast majority of dune activation ages from the Arkansas River valley are younger than 2000 cal. yrs B.P.
- Of those ages, most are younger than 500 cal. yrs B.P.
- This pattern suggests that younger episodes of dune activity have overprinted much of the older episodes of activity.

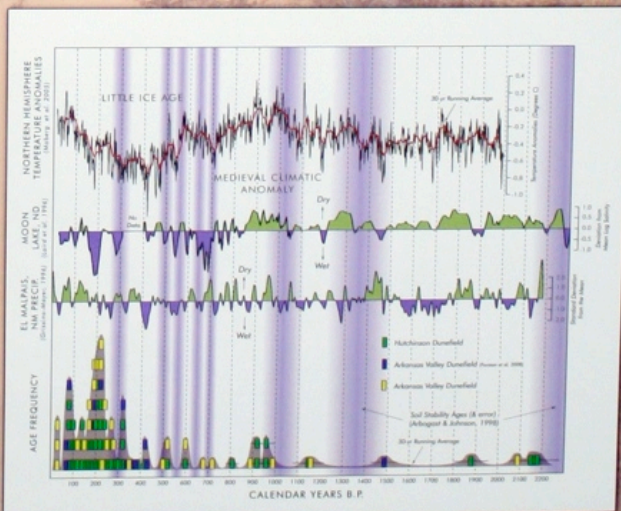

- Further evidence of younger dunes overprinting older dunes can be observed in the individual morphology of many dunes in the Arkansas Valley Dunefield.

Top-down (left) and oblique (right) views of transverse dunes in the Arkansas Valley Dunefield. Younger, south-trending dunes are clearly overprinting older, north-trending transverse dunes in both images.

## CLIMATOLOGICAL IMPLICATIONS

- Dune activity in the Arkansas River Valley appears to be coeval with major climatic shifts, most notably, the Medieval Climatic Anomaly and the Little Ice Age.

## ACKNOWLEDGEMENTS

We would like to acknowledge Paul Hanson (University of Nebraska-Lincoln) and Joel Spencer (Kansas State University) for assisting in the production of the optical ages used in this presentation. We would also like to thank Terri Woodburn for assistance in the field. Finally, we thank the numerous landowners who provided sampling access. This project was funded by the National Science Foundation (SBE-1030254), the United States Geological Survey EDMAF and STATEMAP Programs, the Geological Society of America, the American Philosophical Society, and the University of Kansas.

# RECONSTRUCTING HOLOCENE EUROPEAN LAND COVER USING DATA-MODEL INTEGRATION

Achille Mauri, Jed O. Kaplan, Basil Davis

XVIII. **INQUA BERN 2011**  
SWITZERLAND

## Introduction

European land cover changed substantially during the last 12,000 years as a result of both changing climate and human impact. In particular, the transition from hunter-gatherers to agro-pastoralists led to profound changes in terrestrial ecosystems through deforestation, cultivation, grazing, irrigation and fire.

To investigate these issues land cover reconstructions are needed. Previous attempts have been limited by: availability of primary data, availability of methods for interpolating palaeoecological records in space and time, and lack of coordinated efforts between paleoecologists and modelers.

Within the ARVE group, we tackled these problems by developing a new method for mapping past land cover based on an innovative synthesis of palaeoecological data and vegetation modeling.

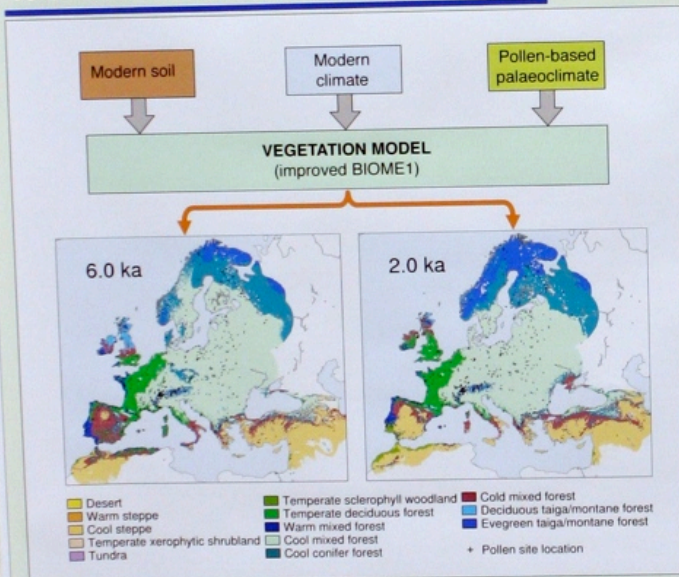

## Methods

The maps of **actual land cover (3)** are a combination of **potential natural vegetation (1)** and **anthropogenic land use (2)** maps.

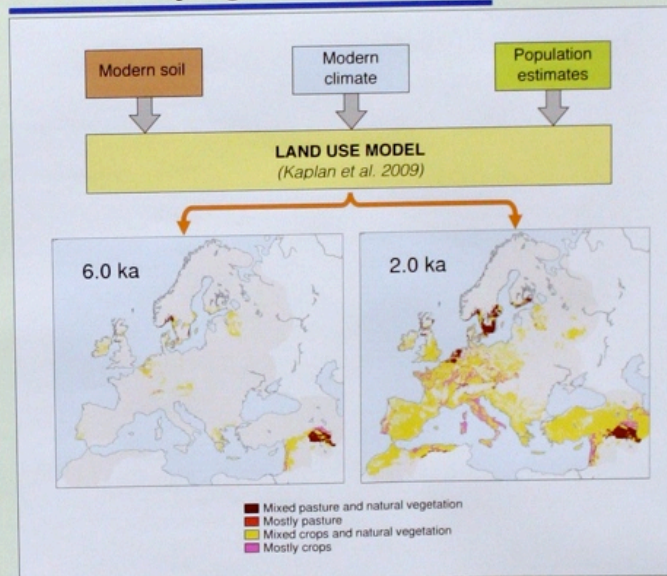

**Potential natural vegetation (1)** maps are produced by using a vegetation model (improved BIOME1) driven by soil properties and pollen-derived palaeoclimate. The use of pollen-derived palaeoclimate circumvents the use of global climate model output that has been used in other studies, but which is known to be problematic in certain regions.

**Anthropogenic land use (2)** maps were produced by developing a model of land exploitation based on changing population and agricultural technology. The model is applied to maps of land suitability for crop and pasture assuming that the best land is cleared first.

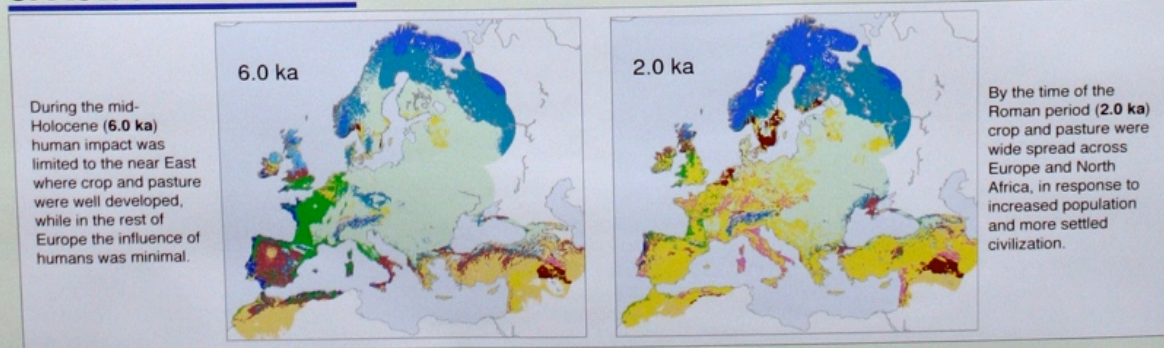

## 1. Potential natural vegetation

## 2. Anthropogenic land use

## 3. Actual land cover

## Conclusions

By combining maps of **potential natural vegetation (1)** and **anthropogenic land use (2)**, we produced high-resolution maps of European **actual land cover (3)** for the entire Holocene.

This will allow us to address a number of research questions, including:

- The time history of human impact in relation to conservation, biodiversity, and land degradation.
- The timing of the spread of civilization throughout Europe.
- The impact of land cover change on terrestrial hydrology and carbon and nutrient cycling.

## Future work

• Land cover maps will be produced for the entire Holocene using a time step of 500 years.

• Land use maps will be optimized by taking into account archaeological data and pollen-based land use intensity maps for crop and pasture.

• Potential natural vegetation maps will be evaluated using leave-one out cross-validation. This involves systematically removing each pollen sample from the training set and then predicting its observed climate and vegetation using the remaining pollen samples (n - 1).
